

Bonus question 2

1. the value in the child process will be the same as the parent process because it is set before fork. If the value of x is 100 in the parent then the child's x variable will also be 100. If the variable is changed in parent before the fork it will be the same in child if it is changed in the child program it will not affect the parent.
2. If a program opens a file with `open()` then calls fork to create the new process then both processes will have access to the opened file. If both parent and child write to the file at the same time you will run into issues with which value is actually in the file as both programs are overwriting each others write to the file.
